20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

This report presents a formal top level interface specification of a kernel for a secure communications processor based on a Honeywell Level 6/40 minicomputer enhanced with a security protection module (SPM).

DD FORM 1473 EDITION OF 1 NOV 65 IS OBSOLETE
1 JAN 73

PREFACE

Because of funding limitations, the Air Force terminated the effort
which this document describes before the effort reached its logical
conclusion. This report is incomplete, but was published in the
interest of capturing and disseminating the computer security tech-
nology that was available when the effort was terminated.

This report describes the top level design of a security kernel for
a secure communications processor. Although the kernel described in
this report should be useful in a wide range of minicomputer appli-
cations, the kernel was initially intended for use in the front-end
processor of a secure, general purpose computer system (Multics).
In general, the kernel functions described in this report appear
adequate. The Air Force review of this document included comments
on particular design issues and the style of specification and the
resulting impact of this style on verification of the design. Because
sufficient funds to completely revise the report were not available,
the outstanding comments appear in an appendix.

ACKNOWLEDGMENTS

TABLE OF CONTENTS

1.0 INTRODUCTION

This report presents a formal top level interface specification of a kernel for a secure communications processor based on a Honeywell Level 6/40 minicomputer enhanced with a security protection module (Reference 3). This kernel provides access controls to support the security and integrity access policies as defined in the Bell and LaPadula model (Reference 1).

This specification is intended to be suitable for formal proof of correctness. The specification is written in the formal specification and assertion language, SPECIAL, developed by Stanford Research Institute (Appendix B).

Implementation of this specification is intended to support both secure front-end processor applications and general-purpose stand-alone communications applications.

2.0 SPECIAL OVERVIEW

The following description is intended to serve only as an overview of some of the basic features of SPECIAL. For a complete description of the language, the reader is referred to the SPECIAL reference manual written by Stanford Research Institute and included as Appendix B of this document.

SPECIAL allows for the definition of abstract data objects and operations performed upon these objects. The objects are represented as V-functions, i.e., functions that return a value. The collection of V-functions represents the state of

1

the system being specified. Operations on objects are represented by O-functions. O-functions modify the values of V-functions and thereby change the state of the system. A third class of functions is that of OV-functions, i.e., functions that both change the system state and return a value.

A distinction among V-functions is that they can be either primitive or derived. The value of a derived V-function is simply an expression in terms of other V-functions. Only the values of primitive V-functions can be changed by O-functions and this implicitly changes the values of related derived V-functions.

A second distinction among V-functions is that they can be either visible or hidden. A visible V-function is one that is available to the outside world. A hidden V-function can only be referenced from within other functions. By convention, the names of all hidden V-functions contained in the kernel specification begin with the prefix "h_".

An individual function specification comprises several different parts. For visible functions, the first part is always a list of exception conditions, i.e., conditions under which the function fails to operate or return a value. These exceptions apply only when a visible function is referenced from the outside world. When referenced internally, i.e., from within another function, exceptions are ignored. Similarly, hidden functions, which can only be referenced internally, have no exceptions. The order of exceptions is

2

significant. Each exception condition is checked in turn, and
only if all the conditions are false will the effects take
place and/or the value be returned. The calling program may
depend on the order in which the exception conditions are
checked. The remaining parts of a function specification
differ for V-functions and O-functions. In the case of a V-
function, the specification contains either an initial value
for a primitive V-function or the derivation expression for a
derived V-function. O-functions and OV-functions contain a
list of "effects" that describe changes to V-functions. For
an OV-function, the effects also define the output value. The
order of effects within a given list is unimportant. All
effects occur at once, i.e., instantaneously. Within an
effects list, references are made to the old and new values of
V-functions, i.e., the values before and after the effects have
occurred. The new value of a V-function is indicated by a
single quotation mark (') preceding the V-function name.

The entire set of functions which constitute the top level
specification are divided into groups called modules. The
purpose of modules is to allow the specifier to conveniently
organize a possibly large number of functions into small
groupings that can be easily understood. The modularization
serves no other purpose. Often, the modules may, in some ways,
correspond to actual program modules in a perceived implementa-
tion. This, however, is not necessary.

Function references between modules are permitted. A function
of one module can observe the value of V-functions, including

3

hidden V-functions, of any other module. However, V-functions
can only be directly modified by O- or OV-functions of the
same module. Therefore, in order for one module to change
a V-function of another module, the first module must invoke
an O- or OV-function of the second module.

The specification of a module is divided into six sections
as follows:

1. TYPES

   This section defines new data types which supplement
   the primitive data types of the language.

2. DECLARATIONS

   This section defines variable names and their associated
   data types.

3. PARAMETERS

   This section defines named constants which, in SPECIAL,
   are called parameters.

4. DEFINITIONS

   This section allows for the specification of macros.

5. EXTERNALREFS

   This section defines all external functions referenced
   within the module.

6. FUNCTIONS

   This section contains all of the individual function
   specifications for the module.

3.0   SECURITY KERNEL SPECIFICATION OVERVIEW

   The SCOMP kernel specification is divided into the following
   modules:

4

- clock
- access_levels
- processes
- volumes
- quota_cells
- segments
- devices
- address_spaces
- host_interfaces

Each module takes the form of an object manager; i.e., each module defines the data representation and operations for a particular object type.

The functions of these modules define the top level kernel interface. The visible kernel interface includes all non-hidden V-functions and all O- and OV-functions not specifically excluded from the interface by the SCOMP-kernel interface specification which precedes the module specifications.

The SCOMP-kernel interface specification identifies the modules that compose the interface and, for each module, identifies the O- and OV-functions that are excluded from the interface. Unlike the module specifications, the interface specification is not written in SPECIAL, but is written in a specific interface specification language also developed by Stanford Research Institute. Functions excluded from the interface are specified following the WITHOUT clause for each module.

4.0 SCOMP KERNEL MODULES

4.1 Clock

The first module of the SCOMP kernel specification describes
the system real-time clock. The read_real_clock function
returns the current value of the system real-time clock. The
clock is used as a source of unique identifiers by the various
kernel modules.

4.2 Access Levels

The access_levels module serves to define the internal
structure of an access level. An access level is composed
of both a security level and an integrity level. A security
level or an integrity level is composed of both a level number
(e.g., confidential, secret) and a category set (e.g., NATO,
crypto).

The access_levels module contains functions for determining
subject access (read, write, or read/write) to an object.
These functions implement the nondiscretionary access control
policies of the security model (simple security and the
*-property). The functions take as input a subject access
level, an object access level, and a boolean value indicating
whether the subject is trusted. All access control decisions
made by the kernel depend on these functions.

4.3 Processes

The processes module is concerned with the creation and dele-
tion of processes, interprocess communication, process sched-
uling priority, process virtual clocks, and process real timers.

At process creation, the access level of the new process, the trusted or untrusted status of the new process, and the scheduling priority of the new process are specified. Process creation and deletion are restricted to the trusted initializer process only. For this reason, process creation cannot serve as an information path between untrusted processes. Therefore, knowledge of the existence of processes is not restricted.

The processes module provides an interprocess communication mechanism via the block, read-messages, send-signal, and wake-up functions. The send-signal and wake-up functions insert a message into the target process message queue. If the target process state is blocked, the process state is changed to ready. The difference between signals and wake-ups is that a signal is recognized immediately by the receiving process whereas a wake-up is not recognized until the receiving process next invokes the block or read_messages functions. The block function allows a process to read its message queue; if the queue is empty, the process is blocked (state changes to block) until a message arrives. A read_messages function is provided that simply reads any pending messages, but will not wait for a message to arrive.

The processes module supports the process scheduling mechanism, which is hidden within the kernel, by maintaining the scheduling priority of each process. Process priority is modified via the set_priority function. A process may

change its own priority without any restrictions being imposed by the kernel; however, the priority of another process may only be increased. The purpose of this mechanism is to allow a process to associate a message with a priority. A message may be sent to another process via the wake-up or send_signal functions. The sender may then request that the scheduling priority of the target be changed to that of the message. If the message priority is greater than the current target process scheduling priority, its priority is raised to that of the message.

The process module supports real-time timers; the kernel maintains one real timer per process. If additional timers are required by a process, they must be managed by the clock manager portion of the supervisor. When a timer is set, the caller specifies the timer-interval, a wake-up message (timer identifier), and the interrupt level at which the clock manager is to run. When a timer runout occurs, the target process is sent a wake-up message and the corresponding timer level indicator is set. Upon process dispatch, the process will execute the level handler corresponding to the highest priority level indicator which is set.

The processes module also supports a per process virtual-time clock which only runs when the process state is running. Ideally, process virtual time represents the real time that a process has actually been running on a processor with subtractions made for certain hidden events such as page

8

faults and interrupts. The objective is to factor out time spent performing hidden operations that support the virtual process environment because this time is unpredictable and, in general, depends upon the activities of other processes. The implementation of this ideal virtual clock is difficult. Thus, the kernel allows access to the virtual clocks only to the trusted time-monitor process for accounting purposes.

4.4   Volumes

The volumes module is concerned with the creation and deletion of volumes, and the mounting and demounting of volumes. Volumes are considered a logical subdivision of secondary storage consisting of a single disc pack.

At volume creation, minimum and maximum access levels for the volume are specified. These access levels define the range of access levels of information (i.e., segments) that can be stored on the volume. The minimum access level of the volume also serves as a visibility access level for the volume. Volume creation and deletion are restricted to the trusted volume initializer process to allow a limit to be placed on the number of volumes without creating an information channel. At volume creation, an initial quota cell and quota cell limit are created for the volume. The quota value of the initial quota cell is set to the volume size (i.e., the number of pages on the volume). The quota limit value of the initial quota cell limit is set to the number of allowed quota cells per volume. Details on quota cells may be found in the description of the quota_cell module.

9

The only operations which can be performed on a volume by untrusted processes are mounting and demounting. Both of these operations require that the caller's access level be equal to the volume minimum access level because the mounting and demounting of a volume can be detected by any process at an access level equal to or greater than the volume minimum access level. To prevent the creation of an information channel caused by the finite number of disc drives in the system, disc drives are allocated by access level. The kernel requires that for a process to mount a volume on a disc drive, the process access level, the volume minimum access level, and the drive access level must all be equal. The access level distribution of free disc drives may be changed dynamically, if necessary, by the trusted initializer process using the change_drive_count function.

4.5   Quota Cells

The quota_cells module is concerned with the management of volume quota and provides the mechanism to build a hierarchical file system outside the kernel. Quota cells are the mechanism by which the sharing of pages on a volume is controlled - each segment is assigned to a particular quota cell. The kernel provides a general interface that allows any arbitrary collection of segments having the same access level to be assigned to the same quota cell. The supervisor (i.e., file manager) is responsible for imposing an arrangement of quota cells and segments that reflects a directory hierarchy.

At quota cell creation, a volume, an access level, and a visibility access level are specified. The two access levels must be within the volume range. Storage space on a volume is first made available by the creation of an initial quota cell at volume creation. Both the access level and the visibility access level of the initial quota cell must equal the volume minimum access level permitting the initial quota to be distributed to higher access levels as needed. All other quota cells are created with a quota of zero pages. In order to assign a nonzero quota to a new quota cell, quota must be moved from some other quota cell on the same volume. Quota cannot be moved downward by untrusted processes - the move_ quota function requires that the target quota cell have an equal or greater access level than the source quota cell; only trusted processes may move quota downward.

A reference count is associated with each quota cell. This count is the number of segments that charge pages to the quota cell. As long as this count is nonzero, the quota cell cannot be deleted. Another attribute of a quota cell is the count of pages used. This count is changed by the creation and deletion of segments (segment length is converted to equivalent pages) as specified in the segments module. For all quota cells, the pages used count is not permitted to exceed the quota.

To prevent the creation of an information path resulting from shared finite resources, a limit is placed on the number of quota cells that can be created on a volume. At volume

creation, the volume quota cell limit is assigned to the
volume minimum access level permitting the volume limit
to be distributed to higher access levels as needed. All
other access levels quota limits are initially zero. In
order to create a new quota cell with a visibility access
level greater than the volume minimum access level, the
quota cell limit must be redistributed from some lower
access level limit on the volume. The quota cell limit
cannot be moved downward by untrusted processes - the
change_quota_cell_limit function requires that the target
quota cell limit have a greater visibility access level than
the source quota cell limit; only trusted processes may
change quota cell limits downward.

4.6   Segments

The segments modules is concerned with the management of
segments, the logical unit of storage for SCOMP. Within
this module, segments are identified by global identifier
only; the local process view of segments are identified by
segment number, as defined in the address_spaces module.
The segments module also specifies the interface for the
SCOMP memory manager process which is responsible for all
memory manager policy decisions.

At segment creation, a visibility access level, a volume,
a quota cell, and a segment length must be specified. The
new segment resides on the specified volume and charges
its pages to the specified quota cell. The access level
of the new segment is equal to that of its associated quota

12

cell. The number of pages charged to its quota cell is derived directly from the requested segment length; initially all words of a segment have a value of zero. Only paged segments may be dynamically created by a user; no main memory allocation is made at segment creation. No limit is placed on the number of segments that can be created on a given volume.

For flexibility, a memory manager interface has been included in the kernel specification in the segments module. The memory manager is to be an untrusted process running at system high which is responsible for all memory management policy decisions; the kernel provides the mechanisms for implementing its policy decisions. Thus, policy may change without affecting the kernel.

The memory manager interface must be flexible in order to accommodate the various operating environments for SCOMP. That is, the kernel specification must be applicable to the following configurations:

- High performance, core-only system with sufficient memory to preallocate memory at load time; for performance reasons, unpaged segments are utilized as much as possible.

- High performance, core-only system with insufficient memory to preallocate all data buffers at load time; thus, a simple buffer manager is required.

- Medium performance, disc-supported, fully-paged virtual memory system with a general memory management function.

13

The kernel specification satisfies the requirements imposed by the various configurations, yet retains a simple user interface, by imposing the following rules and conventions:

- Paging is invisible to all user processes; visibility of paging is restricted to the memory manager. The only reason for the visibility of paging effects within the specification is to support the memory manager interface.
- Unpaged segments must be defined at load time and retained in core until deleted; only paged segments are subject to dynamic memory management.
- The allocation of real memory to requestors is postponed as long as possible by the kernel; no real memory is allocated until the user attempts to access it.

The kernel design envisioned is as follows:
- The kernel has a free list of available memory pages from which it draws to satisfy access requests (allocate_page function).
- When the number of free pages falls below some fixed threshold (min_free_page_count), the external memory manager is requested to provide additional pages (page_request_count).
- When the kernel is unable to satisfy an access request, the requestor is delayed until free resources are available (as supplied by the memory manager).

The kernel specification provides a memory manager interface via two functions: get_memory_data and provide_free_pages. These functions are only available to the memory manager.

14

The get_memory_data function provides a list of pages eligible for memory deallocation. The memory utilization data consists of the global segment name, the page number, the page core address, an indication of whether the page has been used since the last time the function was called, and an indication of whether the page has been modified since it was placed in main memory. To be eligible for deallocation, a page must be in core, and not wired. The provide_free_pages function notifies the kernel of the pages selected by the memory manager for deallocation. These pages are swapped to disc if modified and placed on the free list. The data provided by the kernel to the memory manager process appears sufficient to support a reasonable memory management policy, e.g., frequency of page use is provided along with method of access (read or write) - thus, a reasonable policy would be to favor pages used infrequently in a read mode only.

Functions are defined for reading and writing the contents of segments (i.e., read/read). These functions have certain side effects, as well. That is, if the target segment is paged, then the kernel checks the page_in_core indicator. If not in core, a free page is allocated to the process to satisfy the request. If the free page count falls below some minimum threshold, the memory manager is sent a wake-up.

Segment deletion requests are delayed until all outstanding I/O on the segment has completed. Upon satisfaction of this condition, and if no exception conditions are true, pages in

15

core (paged segment only) are added to the free list.
Similarly, an unpaged segment (which must be in core) is
converted to equivalent pages and added to the free list.
The page quota of the quota cell associated with the segment
is increased by the equivalent segment length.

To support memory management, the segments module is re-
sponsible for monitoring pages used, pages modified, and
segments wired on a global basis. Since page descriptors
are to be shared, page used and modified indicators are only
maintained within the segments module, no process local view
of page utilization (within the address_spaces module) is
necessary. However, wired segments are locally known (a
segment must be locally wired to perform I/O). The segments
module's global view of wired segments is derived from the
local data and provides a count of the number of processes
which have the segment wired. The hidden change_wire_count
function is called from address_spaces whenever a segment is
locally wired (wire_seg) or unwired (unwire_seg).

4.7 Devices

The devices module is responsible for the management of
devices. Within this module, devices are identified by global
identifier only; the local process view of devices, where
devices are identified by device number, is defined in the
address_space module. The device module also specifies the
interface for the SCOMP device monitor process.

At device creation, the device access level, the device type, and the device mapping mode are specified. Since all devices are read-write from a security viewpoint (all operations may return status information visible to a using process and may result in a change of state visible to the external world), a process must have an access level equal to that of the device in order to initiate it. The device type is used to define those read and write control operations valid for user processes to perform with the device. The mapping mode specifies whether the device is to operate mapped or premapped. Device creation and deletion are restricted to the trusted device manager process. Similarly, the modification of device attributes (access level and mapping mode) is restricted to the device manager.

For completeness, a device monitor interface has been included in the kernel specification in the devices module. The device monitor process would be analogous to the memory manager process. The get_device_data function provides the necessary interface. The function provides the device utilization data to the device monitor. This information consists of the device global name, a device initiated indicator, an indication of whether the device has been used since the function was last called, and an indicator of whether the device has been written to since the function was last called for all devices which exists in the global device catalog.

The devices module also includes the device_wake-up function
which notifies the device initiator process of asynchronous
I/O termination. When the termination interrupt is received,
the kernel sends the initiator process a wake-up message
consisting of the device local name and sets the correspond-
ing device level indicator which schedules the device handler
for the process.

4.8   Address Spaces

The address_spaces module supports both the binding of segment
numbers to segments and device numbers to devices within a
process as well as the granting and revoking of current access
to segments and devices. In addition, this module provides
kernel interface functions for reading and writing segments
and devices, as well as functions to support trap and level
handling within a process.

The binding of a segment number to a segment is accomplished
via the assign_segno function. The assigned segment number
is selected by the supervisor, not the kernel. Information
about assigned segments is maintained in a per-process table
called the known segment table (kst). The kst is represented
by a collection of V-functions. Similarly, the binding of a
device number to a device is accomplished via the assign_
devno function. The assigned device number is selected by
the supervisor, not the kernel. Information about assigned
devices is maintained in a per-process table called the known
device table (kdt). The kdt is represented by a collection
of V-functions.

18

The assignment of a segment number to a segment or a device number to a device does not make the segment or device directly accessible. Object access is accomplished via the give_access and give_device_access functions for which the caller specifies the access mode and ring brackets for the segment or device. The requested access mode is modified, if necessary, by the kernel to conform to access level restrictions. For device access, a process level must also be defined (at which a device handler must have been previously defined) in order to allow the process execution point to be properly handled during asynchronous I/O termination notification (i.e., device_ wake-up). Any process can grant itself access to a segment or device in this fashion. However, it is expected that the supervisor will control the use of these functions so as to enforce the discretionary access control list (ACL) policy. Similarly, the supervisor will enforce the discretionary ring bracket policy. The kernel requires only that the segment and device ring brackets be outside the kernel ring.

Functions are also provided to revoke the access of all processes to a given segment or device. These functions can be used by the supervisor to force all processes to recompute access to a segment or device after an ACL has been changed. Once access has been revoked, subsequent references to the segment or device will cause an exception. The address_spaces module also includes a revoke_vol_access function. At the time a volume is demounted, access to all segments on the volume is revoked by the use of this function.

The address_spaces module provides two functions, hidden from the kernel interface, which support process creation and deletion. The init_address_space function initializes the new process address space at process creation time. The process kst is initialized to a template_kst and the initial process execution point is defined. This process initialization is identical for all processes. It is envisioned that the new process will then utilize the interprocess communications mechanism to communicate with the initializer process (e.g., answering service process) to obtain sufficient data to establish its process-unique functionality (e.g., create its kdt). The purge_address_space function releases all segments and devices in the address space of the process at process deletion time.

Several functions in the address_spaces module represent either memory reference or device reference operations associated with classes of machine instructions. These functions include:

- Read_seg - reads a word from a segment for process
                - represents all load memory instructions
- Write_seg - writes a word to a segment for process
                - represents all store memory instructions
- Execute_seg - executes a word from a segment for process
                - represents all fetch instruction from
                  memory cycles
- Call - initiates inter-ring inward movement for process
            - represents Link Jump across Rings (LNJR) machine
              instruction

20

- Return - initiates inter-ring outward movement for process
  - represents Return (RETN) machine instructions
- Sync_device_read - reads a word from a device synchronously for process
  - represents all PIO input instructions (IO, IOH)
- Sync_device_write - writes a word to device synchronously for process
  - represents all PIO output instructions (IO, IOH)
- Connect_device_read - starts an asynchronous read operation from device for process
  - represents all DMA input connect instructions (IOLD)
- Async_device_read - asynchronously reads a word from mapped device to segment for process
  - represents DMA transfer from device to memory (IOLD execution)
- Connect_device_write - starts an asynchronous write operation to device for process
  - represents all DMA output connect instructions (IOLD)
- Async_device_write - asynchronously writes a word from segment to mapped device for process
  - represents DMA transfer from memory to device (IOLD execution)

The address_spaces module also includes two functions primarily intended to support secure user-intiated I/O. A segment must be maintained in main memory (no page faults) during DMA I/O to prevent security violations. The function wire_seg provides the mechanism by which a user may insure that an entire segment is in main memory and no longer eligible for deallocation by the memory manager. The function unwire_seg releases a wired segment. The effects of wire_seg are to set a process-local wire indicator (h_kst_seg_wired) on the segment descriptor and a global wire indicator (h_seg_wire_count). The global indicator is used to support the memory manager interface while the local indicator is checked by the hardware before allowing a connect_device operation to proceed. In order to have a process-local mechanism to mediate unwire_seg requests, yet support multiple devices performing I/O on the same segment, an I/O count (h_kst_seg_io_count) is also maintained on the process-local segment descriptor. The I/O count is incremented (by hardware) whenever a DMA transfer is initiated and decremented (by hardware) upon I/O termination (i.e., effects of device_wake-up).

The address_spaces module allows a process to execute at multiple interrupt priority levels within its address space. Three visible functions are adequate to support this capability. The set level handler function allows a user to specify a level handler (i.e., task handler) for a process at a given interrupt priority level. The kernel enforces the

22

discretionary ring bracket policy within this function as
follows: (a) the effective ring of execution of the level
handler cannot be more privileged than the caller ring;
and, (b) if a more privileged level handler already exists,
then the request is denied (if the existing handler is not
more privileged, it is replaced). The modify_activity_
level and the lev functions allow a user to manipulate
the activity level indicators for his process. They repre-
sent the functionality provided by the level change (LEV)
machine instruction. The modify_activity level function
reflects the defer interrupt option of the LEV instruction.
The lev function reflects both the normal LEV instruction
(level context switch) execution and its suspend level option.
The only requirement for these functions is that the level to
be manipulated must have a defined handler. To support the
multiple priority level capability, three functions hidden
from the kernel interface are included. These functions are:
set_level, change_level, and dispatch_level.

The last feature of the address_spaces module is trap handling
or fault processing. The visible trap handling functions allow
nonkernel software to handle traps; certain traps (e.g., page
faults) are not visible at the kernel interface and are not
covered by these visible functions. The trap structure
supported by the SCOMP kernel is a generalization and simpli-
fication of the particular trap mechanism implemented in the
SCOMP hardware. The set_trap_handler function allows the user
to specify a trap handler and trap save area for a particular

trap type for his process. The kernel enforces the discretionary ring bracket policy within this function in a manner similar to level handlers. That is, (a) the effective ring of execution of the trap handler cannot be more privileged than the caller ring; and, (b) if a more privileged trap handler already exists, then the request is denied (if the existing handler is not more privileged, it is replaced). The trap function specifies the behavior of the kernel upon the occurrence of a given trap type. The kernel passes the pertinent trap information into the user defined trap save area and changes the process execution point to the trap handler. The return_from_trap function specifies the return from the user-defined trap handler upon completion of fault processing. The only significant restriction imposed by the kernel within this function is that the ring of execution of the specified return execution point not be more privileged than that of the trap handler; it is not necessary to return to the point where the trap occurred.

4.9   Host Interfaces

The host_interfaces module provides those functions necessary to support secure communication between a host (e.g., Multics) and a front-end processor (SFEP). As specified, the link between the SFEP process and its associated host process is the device name (e.g., terminal) on whose behalf both processes were created. That is, neither the front-end

process nor the host process need be aware of the others process identifier in order to communicate since only one untrusted user process may have a device initiated at any one time. Thus, specifying the device name implies a unique target process.

In order to support the host interface, several kernel data areas are associated with each device, represented by a collection of V-functions. These are:

- device_status_area - Area used by the SFEP process to transmit device status information to the host process.
- device_control_area - Area used by the host process to provide device control information to the SFEP process (e.g., change translation table).
- message_queue - Area used by the SFEP process to send messages to its associated host process.

In addition, each device has a data area or buffer in user space whose location is specified to the kernel when data is to be sent to the host process or when data is to be received from the host.

The following SFEP kernel functions are included in the host_interfaces module to support the host interface:

- send_message - Allows the user to transfer a data buffer (i.e., message) to its associated host process.
- receive_message - Allows a user to specify a data buffer to receive a data message from its associated host process.

25

- read_control_data - Allows a user to read the device control table set by the host process.

- write_status_data - Allows a user to transfer device status information to its associated host process.

- send_wake-up - Allows a user to send a message to its associated host process via its message queue. This function is analogous to the wake-up function which supports SFEP inter-process communication.

- send_host_signal - Allows a user to interrupt the host process to receive immediate attention. This function is intended to support a device "QUIT" mechanism.

SPECIAL

REFERENCE MANUAL

by

Olivier Roubine

and

Lawrence Robinson

(2nd Edition)

Stanford Research Institute
Menlo Park, California

ABSTRACT

This document describes the specification language SPECIAL, which
is a tool developed for the design of large software systems. The
language is based on a methodology using the concept of a hierarchy of
modules, and provides a convenient facility for the description of the
properties of such modules. The syntax of the language is described, as
well as the semantic notions related to its various constructs.

TABLE OF CONTENTS

1. INTRODUCTION

The design and proof of large software systems can be facilitated by their decomposition into modules, as suggested by Parnas (Par 72 a, b). A design methodology based on this idea has been developed at SRI (Neu 74; Rob 75 a, b), and applied to the construction of several large systems, including a secure operating system (Neu 75). A significant aspect of this work is the design of SPECIAL, a SPECIfication and Assertion Language, which is described here.

The reader is assumed to be already familiar with the methodology itself. The concepts underlying the construction of the language are not emphasized here and will be the subject of a forthcoming document.

This manual is chiefly concerned with the syntax of the language and the associated semantic rules. A general presentation of the language and the objects it manipulates is first given. The "paragraphs" that may appear in a module specification are then described. The part of the language concerned with algebraic and arithmetic expressions is described in Section 10. Further sections contain the precedence rules for binary operators and the rules for referencing an object (scope rules).

SPECIAL has evolved through several forms. The present edition of this manual corresponds to the second version of the language.

2. GENERAL PRESENTATION OF THE LANGUAGE

The macroscopic unit expressed in SPECIAL is the specification of a module or of a set of mapping-function expressions. The first word of a specification, MODULE (1) in the former case, or MAP in the latter, provides the necessary distinction.

We are chiefly concerned with module specifications, because specifications of mapping-function expressions use only a subset of the syntax available for module specifications.

----

(1) In the rest of this document, a word written in upper case refers to a SPECIAL reserved word.

A module specification consists of a sequence of paragraphs appearing between the header

        MODULE <symbol>

and the keyword END_MODULE. The paragraphs are entitled TYPES, DECLARATIONS, PARAMETERS, DEFINITIONS, EXTERNALREFS and FUNCTIONS (or MAPPINGS, for mapping function specifications) and must appear in that order. A paragraph starts with a keyword (e.g., TYPES) and ends at the beginning of the next paragraph or at the end of the module. If a paragraph is empty, it must be omitted; i.e., two paragraph titles may not follow each other.

        Thus, the general outline of a module is something like

        MODULE <symbol> (2)
            DECLARATIONS
              .
              .
              .
            PARAMETERS
              .
              .
            DEFINITIONS
              .
              .
              .
            EXTERNALREFS
              .
              .
              .
            FUNCTIONS
              .
              .
              .
        END_MODULE

        The part of the language that deals with the objects of a module specification is known as the specification level; we describe later a more microscopic level known as the assertion level.

----
(2) Names appearing within angle brackets correspond to non-terminals
     of the grammar (see Appendix A); <symbol> is a particular non-
     terminal referring to any identifier that is not a reserved word;
     what is a legal identifier is described in Section 17.

3. THE OBJECTS USED IN THE LANGUAGE

The specification language manipulates several kinds of objects, all of which are "typed".

3.1. Types and Type Definitions

Each object manipulated by the language is associated with a type. For the descriptive purpose of this manual, it is sufficient to consider a type as a set of possible values.(3) An important aspect of the language is the description of the constraints imposed by types on arbitrary expressions. These constraints are the type rules of the language; they describe how operands of various types can be combined with particular operators to form an expression, and what type this expression will have.

The syntactic representation of a type is a type specification, which is a description of the properties of a type as a whole; type specifications are described in Section 5.3.

We distinguish various categories of types and describe them below:

Predefined types: The predefined types of the language are BOOLEAN, CHAR, INTEGER, and REAL.

Designator types: Designator types form a class of objects-- designators--that are tokens for objects manipulated by the system being specified. Such objects may not be used as freely as, let us say, a number. All the objects with the same designator type are maintained by a particular module and can be created only by functions of this module (generally using the primitive NEW--see Section 11.15.).

Scalar types: Scalar types are types explicitly defined as sets of constants such that any two of them are disjoint (see the comments in Section 5.4.), e.g.,

        direction : [left, right];

which defines "direction" as being a type, elements of which can have only one of the values "left" or "right"; those two symbols are implicitly declared as constants of the type "direction" by the type declaration. Note that such types are not ordered sets, and that only two operations are permitted on them: = and ¬=. Objects of a

----

(3) The term possible values should be distinguished from meaningful values, which are the values for which a particular assertion is true. In particular, the range of a function is a subset of the type of its result.

scalar type also correspond to existing objects of the system but are not maintained by a particular module.

Constructed types: The language contains two unary type constructors, SET_OF and VECTOR_OF, used to define sets and vectors of objects of some given type, and two n-ary type constructors, ONE_OF and STRUCT, used to define united types and structured types, respectively. Since we view a type as a set of possible values, ONE_OF corresponds to the union operator on sets, and STRUCT corresponds to the Cartesian product. Note that type constructors apply to types, not to elements: in particular, a set type defined as "SET_OF t" is a type that represents a set of sets; i.e., each element of this type is a set of values of type t.

Subtypes: The notion of subtype corresponds to that of subset: the language provides the possibility of defining a type as an explicit set of constants of some existing type or as the set of the elements in a particular type that satisfy some property. The particularity of these types is that, for the purpose of type checking, they define only objects of the principal type, since it would require at least a theorem prover to verify the closure of a subtype under all the operations defined on the principal type.

The term primitive type refers to types that are sets of primitive values, one another disjoint; they are the predefined, designator, and scalar types. We can now define a type as being a primitive type, a subtype, or the result of the application of some of the type-constructors to a certain number of types.

3.2. Objects

There is a distinction between the objects manipulated by a module and those manipulated by the specification language, the former being a subset of the latter. The objects of a module are functions and parameters (designator and scalar types, although being families of objects rather than objects, are sometimes referred to as objects of the module, principally because they can be referenced in other modules). In addition, the language deals with so-called definitions, formal and result arguments, and locally bound variables. Each object has a name, a syntactic class, a scope, and a type. The syntactic class is either simple or functional; a simple object can be referenced by a single identifier (its name), whereas a functional object is referenced by an identifier followed by a list of "actual parameters" which are expressions of the language. The scope of an object is the part of a module specification where an object can be referenced after having been declared (the concept of declaration is described in the following section); for instance, the objects of a module (functions and parameters) have the entire module specification as their scope.

3.2.1. Functions

A function is an object of the module itself. Its syntactic

class is always functional, and, in addition, a function has to belong to one of three categories. A category is either VFUN, OFUN, or OVFUN, corresponding to the V-, O-, or OV-functions of the methodology. Functions are either described in the module itself or referred to as external by appearing in the EXTERNALREFS paragraph. A function has a (possibly empty) argument list; every time the function is referenced, it must be followed by a list of expressions, the elements of which are in one-to-one correspondence with the formal arguments, the type of the elements being the same for each pair. In the case of a V- or OV-function, the function also has a "result argument" of a certain type. We sometimes mention the type of a function, thereby meaning the type of its result argument.

3.2.2. Parameters

The parameters of a module are objects that receive a value at module initialization and cannot change thereafter. They can be either simple or functional objects, according to whether the value they receive is a simple value or a function (in the mathematical sense). They represent objects that are fixed in one particular module instantiation, but can be different in different instantiations. As already mentioned, parameters are objects of a module, and, as such, their scope is the entire module specification.

3.2.3. Definitions

A definition is a named object that can be textually replaced by a particular expression; it corresponds to what is generally known as a macro. Definitions can be either simple or functional, and they can be declared either in the DEFINITIONS paragraph, in which case their scope is the whole module specification, or in the DEFINITIONS section of a function, in the case of local definitions whose scope is the function specification.

Definitions differ from the general concept of macros in that the expression that is the body of the definition must be a valid expression when it is declared and not just when it is used (the rules pertaining to the use of definitions guarantee the latter condition if the former one is satisfied). This precludes the use of free variables inside definitions. One of the reasons for this handling of definitions is that it generally prevents the same name from standing for two totally different meanings depending on where it is used.

3.2.4. Formal Arguments

These are the variables appearing in the argument list of a function specification. They may be used freely within the function specification. Formal arguments are always simple objects of the language.

3.2.5. Result Arguments

A V or OV-function <u>must</u> have one and only one result argument, a simple object that may be used in the function specification to refer to the value returned by that function.

3.2.6. Locally Bound Variables

Locally bound variables are objects whose binding remains in effect only within particular expressions, such as <u>quantified</u> expressions (see FORALL and EXISTS--Section 11.10.) or set and vector constructors (see Sections 11.7. and 11.8.). Another important use of such variables is in the so-called LET-expressions (see Section 11.13).

4. BINDING AND THE CONCEPT OF DECLARATION

An object of the language is a rather abstract entity: to be manipulated with a minimal degree of convenience, an object must be associated with a name. Note that it does not make any difference, as far as the properties of a function are concerned, whether its first argument is named "a" or "z", provided that the chosen name is used consistently. In addition, an object must have a type and always has a "scope". We are thus confronted with the problem of associating a name with a particular object (e.g., argument), and also of associating an object with a particular type. What one actually does is to associate a name with a type, and a name with an object, which thus receives the type associated with the name.

4.1. Simple and Multiple Declarations

The association of a name with a type is performed by a particular construct of the language known as a <u>declaration</u>. A simple declaration has the form:

    <simple declaration> ::= <type specification> <symbol>

(the syntax for a type specification is described in the next section). An extrapolation of this construct, referred to as a multiple declaration, can be used to associate several names with the same type specification, using the syntax:

    <multiple declaration> ::= <simple declaration>
                             | <multiple declaration> ',' <symbol>

Generally, the association between a name and a particular object (the "binding") is performed implicitly by the place where the declaration of the name appears; for example:

VFUN f1(INTEGER i) -> BOOLEAN b:

means that:

* The name i is associated with the type INTEGER, and is bound to be the first (formal) argument of f1.

* Similarly, the name b is associated with the type BOOLEAN and designates the result argument of f1.

* Lastly, f1 itself is declared as a V-function of the type (INTEGER -> BOOLEAN).

4.2. Global Declarations and Their Use

It is often the case in specifications that declarations are an important portion of the whole specification and that type specifications themselves can be quite complicated. With this in mind, SPECIAL provides the possibility of separating declarations and bindings (sometimes called the "deferred binding" facility), in the case of formal and result arguments and locally bound variables. This separation is achieved by declaring a name (i.e., associating it with a type) in a global DECLARATIONS paragraph (see Section 6), and performing the binding by letting the name alone appear where a declaration was expected. The rules for using deferred binding are described below:

When a declaration is expected, two cases are possible. If there is indeed a declaration, the name is associated with the type appearing in the declaration and is bound to the relevant object, as determined by the lexical position of the declaration; if the name has already appeared in a global declaration, the new local declaration supersedes the global one for the scope of the object. On the other hand, if a single name appears instead of the declaration, the name designates the corresponding object, the latter being associated with the type appearing in the global declaration of the name. It is obviously an error to use a single name instead of a declaration if the name has not appeared in the DECLARATIONS paragraph.

Remark: In the case of formal arguments to definitions and functions, the language allows a list of multiple declarations separated by ';'. However, if globally declared names are used instead of declarations, each name must be followed by a ';', and not by a ','; in other words, an argument list of the form

(INTEGER i, j; BOOLEAN b)

should be written, if i, j, and b had been declared globally

(i; j; b)

5. TYPES

        The TYPES paragraph has two purposes: it allows the user to
introduce the <u>designators</u> of the module and to associate names with
type specifications (thus providing a macro-like facility for types).
The names defined in the TYPES paragraph as particular type
specifications are referred to as "named types".

5.1. <u>Designators</u>

        A user-defined type, or designator, corresponds to a class of
objects that are tokens for abstract objects implemented in the
software system being specified. It must have a name, introduced by
a declaration of the form:

        <symbol> : DESIGNATOR;

The name introduced in this declaration will thereafter be a
primitive type of its own.

5.2. <u>Named Types</u>

        A type, as defined in Section 3.1., may involve an arbitrary
number of type constructors, leading to a complex type specification.
Such a type expression can be named in a statement like

        <type name> : <type specification>;

<type name> is a new identifier that can textually replace the type
specification appearing on the right-hand side of the equal sign.

5.3. <u>Type Specification</u>

        A type specification is the syntactic representation of a
type.

    * A predefined type, a designator or a named type is represented
      by a symbol.

    * A scalar type has a specification of the form:

        <scalar type> ::= "{" <symbol> {"," <symbol>}* "}"   (4)

    * A subtype has the syntax of a set-expression (see Section 11.7)

    * A structured type is defined as:

----
(4) The syntax descriptions used in this manual follow the extended
    BNF conventions described in Appendix A

<structured type> ::= STRUCT '(' {<declaration> ';'}+ ')'

where <declaration> is

<declaration> ::= <simple declaration>
                | <multiple declaration>

Each declaration introduces a name that is associated with a particular component of a structure, a "field".

* A united type specification is:

<united type> ::= ONE_OF '(' <type specification>
                          {',' <type specification>}* ')'

A united type is a peculiar concept: We defined have earlier (Section 3.1.) a primitive type as a set of simple values disjoint from all the other primitive types (in particular, for a purist, the predefined types should include INTEGER and "NON_INTEGER_REAL", with REAL being defined as ONE_OF(INTEGER,NON_INTEGER_REAL)). A united type which is the union of some primitive types is also a set of simple values but is not necessarily disjoint from the primitive types. In addition, the operations defined on the component types are not defined on the united type, with the exception of '=' and '~=' which are defined on any type. The use of objects of united types must abide by certain rules, described later in this document (see in particular TYPECASE--Section 11.12, and coercion rules--Section 14).

* Sets and Vectors: These are constructed types specified by statements of the form:

<constructed type> ::= {SET_OF | VECTOR_OF} <type specification>

The TYPES paragraph contains an arbitrary number of type declarations and might look like:

        TYPES

    capability, unique_identifier : DESIGNATOR;
    machine_word : ONE_OF(INTEGER, capability);
    access_rights : VECTOR_OF BOOLEAN;

the syntax being:

    <types paragraph> ::= TYPES {<type declaration> ';'}+

    <type declaration> ::= <symbol> { ',' <symbol>}*
                             ':' <type specification>

5.4. Additional_Comments

        The following remarks concern the use of scalar types and
subtypes; those may not appear explicitly except when used to define
a named type, which means that any type specification having the
syntax of a set expression may appear only inside the TYPES paragraph
or the EXTERNALREFS paragraph, and within these paragraphs, may not
be embedded in another type specification. In addition, some special
rules apply to the use of scalar types, since some problems might
arise in cases like:

            TYPES

            traffic_light : { green , yellow , red };
            color : { red , yellow , green , cyan , blue , magenta };

Here, we have first to consider "green", "yellow", and "red" as three
constants of type "traffic_light". Then, when seeing the second
declaration, we must realize that "green", "yellow", and "red" are in
fact constants of the type "color" and that "traffic_light" is a
subtype of "color".

        Thus, the definition of a scalar type is the following: A
scalar type specification is a set of literal constants such that
either none of them is ever used in any other type specification in
the text, or some of them are used to define a subtype of the scalar
type, i.e., they appear in a subset of the set_expression defining
the scalar type.

        This definition precludes, in particular, the following
pathological case: Assume that "color" is defined as above, but the
user wishes to introduce a more sophisticated traffic light, to cope
with a particularly dangerous intersection, as:

            traffic_light: { green , yellow , red , left_arrow }

thus creating the problem of defining the type of each of the
constants, since "traffic_light" can no longer be considered a
subtype of "color". Is "green" of type "color" or of type
"traffic_light", or is it "ONE_OF(color, traffic_light)"? Rather
than defining complicated rules to solve this problem, we prefer to
forbid the intermixing of constants of different types (the problem
raised here can be solved by defining a scalar type that is a
superset of both "color" and "traffic_light").

        Some further thought should also be given to the concept of
structured types. One has to realize that these types allow the
manipulation of tuples of heterogeneous objects, but that their
purpose is not to define complex data structures such as trees, as is
ordinarily done in modern programming languages (e.g., Pascal). It
is in fact one of the goals of the methodology, of which SPECIAL is
only a part, to allow the modules themselves to support the
specification of complex data structures, and there is no reason for

those to   be provided directly   by the   language.   Therefore,
recursively defined structured types are not allowed.

6. DECLARATIONS

The DECLARATIONS paragraph contains   declarations (i.e.,
name/type associations) for names the binding of which is deferred,
as described in Section 4.   If the user does not wish to use the
deferred binding facility, the DECLARATIONS paragraph can be omitted.

A declaration associates a name with a type and stays in
effect within the entire module.

The syntax for the DECLARATIONS paragraph is:

<declarations> ::= DECLARATIONS (<declaration> ";")+

with

<declaration> ::= <type specification>
                        <symbol> {"," <symbol>}*

Example:

    DECLARATIONS
BOOLEAN b;
INTEGER   i,j;
capability   c, c1;
SET_OF capability sc;

7. PARAMETERS

Starting with the keyword PARAMETERS, this paragraph contains
declarations for all the module parameters (see Section 3.2.2).
Since parameters of the module can optionally have arguments, the
syntax for parameter declarations is similar to the syntax for global
declarations, with the option of appending a formal argument list
after each symbol:

```
<parameter declaration> ::= <type specification> <symbol>
                            [<formalargs>]
                            {'.' <symbol>[<formalargs>]}* ';'

<formalargs> ::= '(' [<declaration> {';' <declaration>}*] ')'
```

8. DEFINITIONS

Definitions are syntactic shorthands for arbitrary expressions. They are defined in the DEFINITIONS paragraph; that is, the name of a definition is associated with the expression for which it stands by a declaration of the form:

```
<definition> ::= <typespecification> <symbol> [<formalargs>]
                 IS <expression> ';'
```

The type specification must correspond to the type of the expression, this redundancy being considered beneficial to the clarity of specifications. The expression appearing in the definition may reference only the formal arguments, if any, and the objects that are bound globally, i.e., parameters, global definitions and functions.

The list of formal arguments may be omitted, or may be present but empty; there is a difference in that a definition with an empty argument list must be referenced as a functional expression throughout the specification (e.g., "foo()"), whereas a definition with no argument list must be referenced as a simple term (e.g., "fie"). There is no semantic difference between these two cases, the only difference being purely syntactic.

9. EXTERNALREFS

Although the decomposition of a software system into modules is intended to abolish the intermodule assumptions at the specification level, this is not always possible. A mechanism for referring to the functions, parameters, and designator or scalar

types of other modules is therefore needed in order to describe these
intermodule assumptions. This is the purpose of the EXTERNALREFS
paragraph.

The paragraph itself is divided into as many groups as there
are references to different modules. Each group starts with the
header:

    FROM <symbol> :

where <symbol> is the name of an external module, and the group
contains a list of declarations and/or function headers.

A declaration has the regular declaration syntax, as in
Section 6, or the syntax of a designator or scalar type declaration,
as described in Section 5.

A function header is

    { VFUN | OFUN | OVFUN } <symbol> <formalargs>
                ['[' <declaration> {';' <declaration>}* ']']
                ['->' <declaration>] ';'

If the first term is VFUN or OVFUN, then the result part (i.e., '->'
<declaration>) should be present, and not for OFUN.

As will be shown, this syntax is also used to begin internal
function specifications.

    Example:

        EXTERNALREFS

    FROM capabilities:
    capability, unique_identifier: DESIGNATOR;
    access_type: { read , write , execute , modify , append };
    OVFUN create_capability() -> c;
    OVFUN restrict_acces(capability c1,
                        VECTOR_OF access_type atv)
                            -> capability c;
     VECTOR_OF access_type atv;
    VFUN get_uid(c) -> unique_identifier u;

    FROM segments:
    OVFUN create_segment(INTEGER i,
                        VECTOR_OF capability siv)
                            -> capability s;
    VFUN h_seg_exists(unique_identifier u) -> BOOLEAN o;
    INTEGER maxsegs;

10. FUNCTIONS

The FUNCTIONS paragraph contains the specifications for all the functions of the module and is therefore its most important part.

The methodology deals with OFUN, OVFUN, and VFUN which all have their particularities, although also some common points.

A function definition consists of a header, possibly a set of local macros in a DEFINITIONS subsection, and other subsections which will be characterized for each class of function.

10.1. The Function Header

Similar to that described in Section 9, it looks like

```
{ VFUN | OFUN | OVFUN } <symbol> <formalargs>
            [ '[' <declaration> {';' <declaration>}* ']' ]
            [ '->' <declaration> ] ';'
```

As in definitions or external references, any of the formal arguments, as well as the result argument, may have been declared in the DECLARATIONS paragraph and thus not be preceded by a type specification.

10.2. Implicit Arguments

The optional list of declarations enclosed within square brackets in the function header is the list of "implicit arguments". An implicit argument to a function is an argument that should be provided by the system, and not by the user, when the function is called (in the actual implementation). In terms of specifications, any reference to a function that has been defined with implicit arguments should contain as many actual arguments as the sum of the number of formal and implicit arguments appearing in the function header.

Example:

A function whose header is:
    VFUN f(INTEGER i)[process_id p] -> INTEGER];
may be referenced as a function of two arguments, e.g.,
    f(0, p1)

10.3. Local Definitions

By introducing a section with exactly the same syntax as the DEFINITIONS paragraph, the user has the possibility of defining macros that are known only inside one function specification. Such definitions have the advantage of being able to reference the arguments of the function that have only a restricted binding.

10.4. The Subsections of a V-function

The two remaining sections of a V-function describe its formal properties. A V-function may be visible or hidden, and-- independently--derived or primitive.

If a V-function is visible, it may be referenced in programs outside the module, so a list of exception conditions must appear in the function specification. This EXCEPTIONS subsection is similar to the one appearing in O- and OV-function specifications and is detailed in Section 10.5.

On the other hand, a hidden V-function may not be called outside the module and needs no EXCEPTIONS subsection. In such a case, the reserved word HIDDEN appears in its place.

The last subsection of a V-function specification can either define the initial value of the V-function (for primitive V- functions) or explicitly describe the functions value in terms of other objects of the module (for derived V-functions).   The former case is described through an assertion of the form

        INITIALLY <expression> ';'

where <expression> is an arbitrary Boolean expression. In the latter case, the syntax is

        DERIVATION <expression> ';'

Here, the expression must have the type of the result argument of the function.

comments:

  * The set of all primitive V-functions entirely defines the
    current state of the machine described by the module.   The set
    of their initial values thus defines the initial state of the
    module.

  * Derived V-functions are often used to restrict or to package
    the information visible outside the module.

  * Note that a V-function that is both hidden and derived is very
    similar to a global definition.

The general syntax for a V-function specification is thus

```
        VFUN <symbol> ([<declaration> {"," <declaration>}* ])
                                    -> <declaration> ";"
        [DEFINITIONS [ <definition> ";" }+ ]
        {HIDDEN ";" | [ EXCEPTIONS [ <expression> ";"}+ ]}
        [INITIALLY | DERIVATION} <expression> ";"
```

10.5. The Subsections of O- and OV-functions

As opposed to V-functions, O- and OV-functions are always visible(5) and consequently may have an EXCEPTIONS subsection. Since both perform some operations that affect the state of the module, they also have an EFFECTS subsection.

10.5.1. The EXCEPTIONS Subsection

This subsection contains a list of conditions that, if any is satisfied (i.e., evaluates to TRUE when the function is called), should prevent any effect from taking place and/or any value from being returned. If an exception condition is raised, control is returned to the calling program with "appropriate" notification to the caller. Exactly how this notification is made depends on the conventions of the programming language; we mention here only the constraints imposed by the specification language.

An exception condition is a Boolean expression; the order in which the conditions are listed is important: The meaning of the EXCEPTIONS subsection is that each condition should be checked in turn, and only if all the conditions are false should the effects take place and/or the value be returned. The calling program may depend on the order in which the exception conditions are checked. For example, a reasonable EXCEPTIONS subsection might be:

```
        EXCEPTIONS
    h_interrupt_set(i) = FALSE;
    h_int_handler_offset(i) = ?;
```

(where the two functional expressions are likely to be V-function references), which might mean that i does not refer to any interrupt in the first exception and that, if it indeed does, no interrupt handler exists for it in the second exception; this illustrates that the second exception might be meaningless had not the first one been checked before.

There is also a particular construct intended to be applied only in the EXCEPTIONS subsection:

```
        EXCEPTIONS_OF <call> ";"
```

where <call> should be a reference to an external function. The

----

(5) Probably the only justification for this fact is that the need
    for hidden O or OV-functions has not yet been felt.

interpretation of this construct is that for each exception condition of the external function, there exists a logically equivalent exception condition in the current function. The order in which the exceptions appear in the external function is preserved, and the corresponding conditions are to be checked after all those that precede the "EXCEPTIONS_OF" expression.

The syntax for the EXCEPTIONS subsection can be described as

```
<exceptions> ::= EXCEPTIONS { <expression> ';'
                            | EXCEPTIONS_OF <call> ';' }+
```

Note that this expression forces at least one expression to occur in the EXCEPTIONS subsection; if the function has no exception, the whole subsection should be omitted.

10.5.2. The EFFECTS Subsection

The EFFECTS subsection contains a list of assertions that are Boolean expressions and have the following meaning: If the function is referenced and no exception is detected, then, after the function call, the conjunction of all the assertions appearing in the EFFECTS subsection may be assumed to be TRUE.

If the EFFECTS subsection of function f contains the assertions a_1, a_2,...,a_n, i.e., looks like

EFFECTS a_1; a_2;...; a_n;

and the EXCEPTIONS subsection refers to e_1,...,e_m (i.e., EXCEPTIONS e_1; e_2;...;e_m;) then, using Hoare's notation, a reference to the function f has the meaning

NOT(e_1 OR e_2 OR...OR e_m) {f} a_1 AND a_2 AND...AND a_n

Note that, in the EFFECTS subsection, the order of the assertions is irrelevant.

In the case of an OV-function, one of the assertions might state the equality of the result argument with some expression, thus defining the value returned by the function, but this is not mandatory; the result argument should, however, appear in at least one of the effects, in order not to be undefined.

10.5.3. The DELAY Conditions

In addition to the EXCEPTIONS and EFFECTS subsections, an O- or OV-function may contain an arbitrary number (although generally only one) of so-called DELAY expressions which have the syntax:

DELAY UNTIL <expression> ';'

where <expression> must be Boolean, and the conjunction of all the
delay conditions can be taken as an input assertion to the function;
in other terms, this means that the affects will not take place until
all the conditions evaluate to TRUE.

This concludes our description of the macroscopic or
specification level of the language. The microscopic (or assertion)
level deals with the kind of construct we have been so far referring
to as <expression> or assertion, with the distinction that an
assertion is an expression of type BOOLEAN. This part of the
language is described next.

11. EXPRESSIONS

The assertion language has a relatively large set of syntax
rules for writing concise mathematical expressions to describe
conditions related to a function behavior. In certain cases, the
semantics associated with these rules may require a detailed
description. This section explores the different constructs used in
mathematical expressions; an interesting aspect to be considered is
the set of type rules associated with each operator.

11.1. Atomic Expressions

These are the simplest kind of expression (from the syntactic
standpoint); an atomic expression can be one of the following:

* Numeric constant: A numeric constant may be either of type
  INTEGER (any nonempty sequence of digits), or of type REAL (a
  string of digits followed by a period followed by another
  string of digits followed by the letter E followed by an
  optionally signed string of digits, where either the integer
  part or the fractional part may be omitted, and the decimal
  point or the exponent may also be omitted--but not both).

* Character and string constant: A constant of type CHAR is a
  single, printable ASCII character enclosed within two ` (back
  apostrophe). A string constant has the type "VECTOR_OF CHAR"
  and consists of any sequence of printable ASCII characters
  enclosed within two " (double-quote). The precise rules
  concerning character and string constants may depend on the
  implementation (see Section 17).

* Boolean constant: These are the keywords TRUE and FALSE.

* Symbolic constant: Any identifier appearing in a scalar type

declaration will subsequently be considered a constant of that
type. In addition, the two symbols UNDEFINED and ? are two
synonyms which, for each type, refer to a particular value of
that type, different from any other value (the particular type
is determined by the context where they appear). It is a part
of the verification task to check that the implementation of
any visible V- or OV-function can never return the value
UNDEFINED.

* Reference to an object: The name of any object that has a
  binding and whose syntactic class is not functional is an
  atomic expression whose type is that of the object. Such
  references can be to parameters or definitions when they have
  been declared without arguments, formal arguments of functions
  and definitions, result arguments of V- and OV-functions, and
  simple variables within expressions where they have a binding
  (i.e.,   within set and vector constructors, quantified
  expressions, and expressions starting with LET or SOME).

11.2. V-function References

A reference to a V-function has the form

['] <symbol> <actual list>

where <actual list> is defined as

'(' [<expression> {',' <expression>}*] ')'

and is used as such in the rest of this document. It corresponds to
the actual arguments, which must match in number and type the formal
arguments of the function definition.

<symbol> should be the name of a V-function either defined in
the module or appearing in the EXTERNALREFS paragraph.

The first symbol, ' , is optional. Its meaning, within the
EFFECTS part of a function specification, is that the reference is
made to the value of the V-function immediately _after_ all the effects
of the O- or OV-function being specified have occurred; if it is
omitted, the reference is to the value immediately _before_ the call.
Note that this is meaningful only in the EFFECTS section, since in
any other place there is no distinction between _before_ and _after_, and
in the EXCEPTIONS subsection, a reference is always made _before_ any
effect takes place.(6)

----

(6) We must add at this point an important historic note: Until now,
    all the module specifications derived from Parnas' ideas used
    quoted expressions to refer to _old_ values of V-functions.
    However, this notation could not be used consistently because in
    the same function specification, unquoted references would have
    two different meanings, depending whether they appeared in the
    exceptions or in the effects of the function. Permuting the
    convention takes care of this possible confusion.

The type of a V-function reference is the type of the function itself.

11.3. References to Functional Objects

We deal here with parameters and definitions introduced with an argument list. A reference to such objects has a syntax very similar to that of a V-function reference:

        <symbol> <actual list>

with, for definitions, the usual meaning of a macro expansion, the type being that of the macro, and, in the case of a parameter, that of a mere reference to its value.

11.4. 0- and OV-function References

A reference to an 0- or OV-function is made by the use of the keyword EFFECTS_OF

        EFFECTS-OF <symbol> <actual list>

In the case of 0-functions, this expression is of type Boolean; its value is UNDEFINED if some exception is detected; it is FALSE if the effects of the 0-function that is referenced are never satisfiable. A value of TRUE, on the contrary, means that all the assertions specified in the EFFECTS section of the corresponding 0-function hold.

In the case of an OV-function, the type of the expression is that of the result argument of the function, and the expression itself is both a reference to the value of the OV-function and an indication that all its effects are true at the point where the EFFECTS_OF appears.

The next sections describe the operators used in the language. They are classified by the types on which they operate; the word "mode" appearing in a type description refers to a particular type which does not have to be specified. The discussion concerning precedence of various operators is, however, deferred to Section 12.

11.5. Boolean-Valued Operators

11.5.1. Binary Operators

AND and OR
        Syntax: <expression> [AND | OR] <expression>
        Type: BOOLEAN X BOOLEAN --> BOOLEAN
        Meaning: usual conjunction or disjunction; *error* if one

of the operands is not Boolean.(7)

=>

        Syntax: expression_1 => expression_2
        Type: BOOLEAN X BOOLEAN --> BOOLEAN
        Meaning: usual implication, i.e.,
        (expression_2 OR NOT expression_1) = TRUE
        error if one of the expressions is not Boolean.

    11.5.2. Relational_Operators

=, ~=

        Syntax: exp_1 {= | ~=} exp_2
        Type: mode X mode --> BOOLEAN
            the types of exp_1 and exp_2 may be either:
            any type, provided it is the same for both,(8)
      or: any type for one expression and UNDEFINED for the other,
      or: UNDEFINED for both;
        Meaning: usual = or ≠

<, <=, >=, >
        Syntax: exp_1 { > | >= | <= | < } exp_2
        Type: number X number --> BOOLEAN
        (where number is either INTEGER or REAL)
        Meaning; the usual order relations on numbers.

11.6. Operations_on_Numbers

        The operations on numbers are the usual +, -, * and /, where
- can be either unary or binary; in addition, the operator MOD is
also provided.   The meaning and use do not depart from those
generally encountered. Numbers are either of type INTEGER or of type
REAL. Both types can be intermixed according to the following rules:
A binary operation involving two integers will have the type INTEGER,
and an operation where at least one of the operands is real will have
the type REAL.   In particular, the operator /, when applied to two
integers, will y.eld the integer part of the quotient of the two
operands, whereas if one of the operands is of type REAL, the result
should be the quotient itself.   In addition, some primitives are
provided in the language for specifying the integer and fractional
parts of a real (see Section 11.16.). The use of MOD is restricted
to INTEGER operands.

        All the binary operators on numbers, as well as those on
Booleans, or on sets are left-associative.
----
(7) When the term *error* is used, it does not refer to any
    particular value, but rather means that under the conditions
    associated with it a specification would be incorrect, as far as
    SPECIAL is concerned.   In other terms, it is considered as
    erroneous to say "1 AND TRUE" as to say "DO I = 1, 10" in a
    specification.

(8) For more about type matching rules, see Section 14.

11.7.   Operations on Sets

11.7.1.   Unary Operator

CARDINALITY

        Syntax: CARDINALITY(<set expression>)
        Type: set-mode --> INTEGER
        Value: The number of elements in the set designated by its
        argument

11.7.2.   Binary Operators

UNION

        Syntax: <set expression> UNION <set expression>
        Type: SET_OF m1 X SET_OF m2 --> SET_OF m3
        where m3 is the larger of m1 and m2 if they match, and their
        union otherwise; note that, when the types of the two
        arguments do not match, the result will have the type of the
        minimal union of the two types, e.g.,

        If the type of s1 is "SET_OF INTEGER"
        and the type of s2 is "ONE_OF(SET_OF BOOLEAN, SET_OF CHAR)"
        then s1 UNION s2 will be a
        "ONE_OF(SET_OF ONE_OF(BOOLEAN, INTEGER),
                        SET_OF ONE_OF(CHAR , INTEGER))"

        Meaning: The usual union of two sets.

INTER

        Syntax: <set expression> INTER <set expression>
        Type: SET_OF m1 X SET_OF m2 --> SET_OF m3
        where m3 = m1 if m1 is the same as m2; generates an error if
        m1 and m2 refer to disjoint types, and m3 is the intersection
        of m1 and m2 otherwise.
        Example:

        If s1 is of type "SET_OF ONE_OF(INTEGER, BOOLEAN)"
        and s2 of type "ONE_OF(SET_OF INTEGER, SET_OF CHAR)",
        then s1 INTER s2 is of type "SET_OF INTEGER"

        Meaning: usual set intersection.

DIFF

        Syntax: set_1 DIFF set_2
        Type: SET_OF m1 X SET_OF m2 --> SET_OF m1
        Generates an error if m1 and m2 cannot have any common value.
        Example:

        If set_1 is of type "SET_OF ONE_OF(INTEGER, BOOLEAN)" and
        set_2 is of type "ONE_OF(SET_OF INTEGER, SET_OF CHAR)"), then
        the result will have the type of the first argument.

Meaning: {x | x ∈ set_1 AND x ∉ set_2}

11.7.3. Predicates

INSET

Syntax: <expression> INSET <set_expression>
Type: m1 X SET_OF m2 --> BOOLEAN
Generates an error if m1 and m2 are totally disjoint types
(as with DIFF).
Meaning: The expression is TRUE if the first operand is in
the set represented by the second.

SUBSET

Syntax: set_1 SUBSET set_2
Type: SET_OF m1 X SET_OF m2 --> BOOLEAN
m1 and m2 are subject to the same constraints as with INSET.
Meaning: The expression is TRUE iff set_1 is a subset of
set_2. Note that "s1 SUBSET s2" can be defined as :
FORALL x INSET s1: x INSET s2

11.7.4. Set_Constructors

Explicit Constructor

Syntax: '{' expression_1,..., expression_n '}'
(Here, the curly brackets are actual symbols of the
language.)
Type: If all the expressions have the same type, let us say
t, then the result will be of type "SET_OF t"; otherwise, it
will be "SET_OF ONE_OF(t1,..,t)" where the united-type is
the minimal union of the types of the expressions.
Value: The set S such that:
expression_i ∈ S (i = 1, 2,...,n)

Implicit Constructor

Syntax: '{' <simple declaration> '|' <expression> '}'
Type: <expression> must be Boolean; result is of type
"SET_OF t" where t is the type of the variable appearing in
the declaration.
Value: "{t x | e(x)}" is the set of all x's of type t such
that e(x) is TRUE.

11.8. Operations_on_Vectors

Extractor

Syntax: <vector expression> [<integer expression>]
Type: If the first operand is of type "VECTOR_OF t", the
result will be of type t.
Value: v[i] is the ith component of the vector v.

LENGTH

Syntax: LENGTH(<vector expression>)
Type: VECTOR_OF mode --> INTEGER
Value: the number of components (dimensionality) of its
operand.

Explicit Constructor
        syntax: VECTOR(exp_1,...,exp_n)
        Type: If exp_1,...,exp_n are all expressions of type t, then
        the result will be of type "VECTOR_OF t"; if the types are
        different, the result will be a vector of the minimal union
        of these types.
        Value: V such that
        LENGTH (V) = n   and
        V[i] = exp_i for i = 1, 2,..., n

Implicit Constructor
        Syntax: VECTOR "(" FOR <symbol> FROM <expression>
                        TO <expression> ":" <expression> ")"
        Type: If the last expression always has the type t, then the
        result will be a "VECTOR_OF t" (the expressions following
        FROM and TO must have the type INTEGER). Note that this is
        the only place in the language where a name is bound to an
        object that need not be previously declared; the symbol
        following FOR is a locally bound variable whose type is
        always INTEGER.
        Value: V = VECTOR(FOR i FROM exp1 TO exp2 : f(i))
        is the vector such that:
        LENGTH(V) = exp2 - exp1 + 1   and
        V[i] = f(exp1 + i - 1) for i = 1, 2,...,(exp2 - exp1 + 1)

11.9.   Operations_on_Structures

Extractor
        A reference to a particular field of a structure-expression
        (i.e., an expression whose type is a structured type) can be
        made by appending a "." followed by the name of the
        particular field after the structure-expression itself. The
        syntax is thus:
        <expression> "." <symbol>
        Type: The type is that associated with the field name in the
        structure declaration.
        Meaning: The structure expression being a tuple, the
        extractor refers to the value of the nth element of this
        tuple, if the field name appeared in the nth position in the
        structure declaration.

Explicit Constructor
        Syntax: "<" exp_1,...,exp_n ">"
        Type: t1 X .... X tn
        where ti is the type of the ith expression in the list.
        Value: the tuple whose ith element is exp_i, for i from 1 to
        n.

Implicit Constructor
        Syntax: "<" FOR <symbol> FROM <expression> TO <expression>
                        ":" <expression> ">"
        Type: t X .... X t
        i.e., the n-fold Cartesian product of the type of the third

expression, where n is the difference between the second and
first expressions.
Meaning: The tuple < exp_1,...,exp_n > where exp_i is the
value of the third expression evaluated when the indicial
variable (i.e., the <symbol>) has the value of the expression
following FROM, augmented of i-1.

11.10.   Quantified Expressions

Although quantified expressions are constrained to yield a
Boolean value, they have been placed in this separate section because
of their particular syntax rules.

Universal Quantifier
        Syntax: FORALL {<qualification> | <declaration>}
                         { ';' {<qualification> | <declaration>} }*
                         ':' <expression>

        with: <qualification> ::= {<simple declaration> | <symbol>}
                                   {INSET | '|'} <expression>

        Type: BOOLEAN
        Meaning: as in predicate calculus
        Remarks: The <expression> following the ':' will presumably
        depend on the variables declared after the quantifier. These
        variables are bound locally, only in the last expression (see
        Scope Rules, Section 12). The optional qualification may be
        used to further qualify the variable, without complicating
        the main quantified expression.
        The general way of expressing something such as "for all x's
        such that P(x), Q(x) is true" is:

         FORALL x | P(x) : Q(x)

        whereas "for all x's in the set S, Q(x) is true" would be
        written as:

         FORALL x INSET S : Q(x)

        (Note that, in the two examples above, we used the deferred
        binding facility, presuming that x appeared in the
        DECLARATIONS paragraph.)
        Several variables may be quantified simultaneously, e.g.,

         FORALL x | P(x) ; y | Q(y) : z : R(x, y, z)

        In such a case, each quantified variable may appear in its
        own qualification and in the main (quantified) expression,
        but not in the qualification of another variable.
        The above expression has the following meaning:

         FORALL x : FORALL y : FORALL z : P(x) AND Q(y) => R(x, y, z)

Existential Quantifier
        Syntax:

        EXISTS {<qualification> | <declaration>}
               { ';' {<qualification> | <declaration>} }*
               : <expression>

    Type: BOOLEAN
    Meaning: as in predicate calculus
    Remarks: same as above.

11.11. Conditional Expressions

    Syntax: IF <expression> THEN <expression> ELSE <expression>
    Type: Consider the expression

    IF P THEN e1 ELSE e2

    If e1 and e2 have the same type, that type will be the type
    of the whole expression; if one of e1 and e2 (or both) is
    UNDEFINED or ?, then the type will match anything.   If the
    types of e1 and e2 do not match, then the type of the
    expression will be the union of the type of e1 and the type
    of e2.
    Meaning: x = IF P THEN e1 ELSE e2 is an abbreviation for
    (P AND (x = e1)) OR ((NOT P) AND (x = e2)
    Remark: The ELSE part must always be present!

11.12. TYPECASE Expressions

        This kind of expression is probably the most complex
    construct of the language. It is intended to be used in cases where
    the type of an object used in the system being specified cannot be
    known before execution time.   Its purpose is to allow a temporary
    alteration of the type of an object, from a united type to one of the
    component types. This is particularly desirable because it permits
    the application to the object of some operations that would not be
    defined on the united type without compromising the safety of type-
    checking.

        Syntax:

    TYPECASE <symbol> OF
    type_1:   exp_1;
    type_2:   exp_2;
            .
            .
            .
    type_n: exp_n;
    END

        Type: The type of the whole expression will be the minimal
        union of the types of exp_1,..., exp_n, in the sense that, if
        exp_1... exp_n all have the same type t, then t will be the
        type of the expression, otherwise, the type will be
        ONE_OF(t1, t2,...,tk) where t1,..,tk are all different, and
        are types of exp_1,...,exp_n (in no particular order).

Meaning: The   value   of   the   expression   is   more   easily
understood by using the meta-function "type_of" the value of
which would be the type of its single argument.
Then, for instance

```
a = TYPECASE w of
type_1:   exp_1;
type_2:   exp_2;
type_3:   exp_3;
END;
```

would mean

```
((type_of(w) = type_1) AND a = exp_1)
OR ((type_of(w) ~= type_1
        AND type_of(w) = type_2)
     AND a = exp_2)
OR ((type_of(w) ~= type_1
        AND type_of(w) ~= type_2
        AND type_of(w) = type_3)
     AND a = exp_3)
```

Remarks: There are several restrictions imposed on the use
of this construct. We will call

   * case variable the variable following the keyword TYPECASE;
   * case labels the types type_1,...., type_n;
   * case expressions exp_1,...., exp_n;

   * The type of the case variable must be a united type equal to
     the type that would be obtained by taking the union of all the
     case labels.

   Example: If w is of type

       ONE_OF(INTEGER, BOOLEAN, capability)

   then

```
TYPECASE w of
INTEGER:  w;
BOOLEAN:  IF w = TRUE THEN 1 ELSE 0;
capability:  get_uid(w);
END;
```

   is a valid expression;

```
TYPECASE w of
ONE_OF(INTEGER, BOOLEAN): TRUE;
capability:  FALSE;
END;
```

   is also valid.

(As an illustration, let us mention that the first expression
would have the type ONE_OF(INTEGER, "type_of get_uid"), whereas
the second one would have the type BOOLEAN.)

On the contrary,

```
TYPECASE w OF
INTEGER: 1;
BOOLEAN : b;
END;
```

is incorrect because one of the types is missing.

* Since the expression itself has a type, regular type checking
  is performed.

* When the type of each case expression is evaluated, if the case
  variable appears in the expression, it is taken to have the
  type of the corresponding case label.

11.13. LET Expressions

It is sometimes necessary to bind some variables locally inside a
particular expressions. Yet their use is generally very
limited. When it seems to be really necessary, the user can
declare a list of variables immediately before using them;
their scope is restricted to one single expression, and the
syntax for this construct is:

```
LET <qualification> [ ";" <qualification> }*
        IN <expression>
```

The value and the type of this expression are those of the
expression following the keyword IN. The closest approximation to
the semantics of:

```
y = LET x : P(x) IN Q(x)
```

is something like

```
: x such that P(x) AND (y = Q(x))
```

but this is only an example of the use of this construct.

11.14. SOME Expressions

The SOME construct can be viewed as a kind of set extractor.
The syntax is:

```
SOME <simple declaration> [INSET | ":"} <expression>
```

The meaning of an expression such as

        SOME x INSET S

    is: LET x INSET S IN x

and similarly if "1" is used.

        The following example illustrates the use of this construct:

        EFFECTS_OF wake_up(SOME process p
                                    INSET waiting_processes(sem1))

which might be an assertion inside the specification for a
synchronization primitive.

11.15. The NEW Primitive

        NEW is a special construct that has the same syntax as a
function of one argument:

        NEW "(" <symbol> ")"

where the argument should be the name of a designator type. The type
of this expression is precisely this identifier, and the meaning is
that NEW(t) represents an object of type t that has never been used
before.

        An error will occur if the argument is not a DESIGNATOR (even
an external DESIGNATOR will not work).

11.16. Miscellaneous Operators

        In addition to the various operators and constructs presented
above, the language contains several functional primitives.

MAX, MIN
        Syntax: {MAX | MIN} "(" <expression> ")"
        Type: SET_OF number --> number
        (where number is either INTEGER or REAL)
        Value: the largest (respectively smallest) element in the set
        described in the expression.

SUM
        Syntax: SUM "(" <expression> ")"
        Type: SET_OF number --> number
         or: VECTOR_OF number --> number
        Value: the arithmetic sum of all the elements in the set
        (respectively vector).

INTPART, FRACTPART
        Syntax: {INTPART | FRACTPART} "(" <expression> ")"
        Type: REAL --> INTEGER (resp. REAL)
        Value: These two constructs can be viewed as predefined
        macros:

INTEGER INTPART(REAL x) IS SOME INTEGER y ¦ y <= x   AND y+1
> x;
REAL FRACTPART(REAL x) IS x - INTPART(x);
They define, respectively, the integer and fractional part of
their argument (surprised?).

######

This concludes our syntactic description of the language for
module specifications.   We will now concern ourselves with some
additional precisions concerning the use of certain objects.

12. PRECEDENCE

The large number of operators in the assertion language
requires a precise definition of the precedence ordering, that is, if
op1 and op2 are two operators (let us say binary), we say that op1
has a higher precedence than op2 if

e1 op1 e2 op2 e3

has the same meaning as

(e1 op1 e2) op2 e3

and

e1 op2 e2 op1 e3

has the same meaning as

e1 op2 (e2 op1 e3)

(Note that any expression can always be enclosed within parentheses.)

A general rule is that an operator returning a Boolean valued
expression has always a lower precedence than an operator that
returns another type. This rule is of course insufficient to compare
operators returning the same type of expression.

The ordering is partial, since the operators cannot be freely
combined in the text (e.g., INTER can hardly be compared with +).

The operators are listed in decreasing order of precedence.
Constructs that do not lead to ambiguities (reference to functions,
LENGTH, CARDINALITY, NEW, vector subscripting, TYPECASE, FORALL,

EXISTS, vector and set constructors, LET, and SOME) are not listed, but it should be noted that, when used as operands with any of the operators listed below, the constructs using IF, LET, SOME, FORALL, EXISTS, and TYPECASE should be enclosed within parentheses.

INTEGER	BOOLEAN	sets
unary -		
*, /, MOD		INTER
+, -		UNION, DIFF
	=, ~=, <, <=, >=, >,	
	INSET, SUBSET	
	NOT	
	AND	
	OR	
	=>	

Of interest are the places of NOT, INSET and => : thus

        (NOT x) INSET S

is meaningful only if x has the type BOOLEAN and s is a set of BOOLEAN (for instance {TRUE})

        NOT x INSET s => P(x)

means (x INSET s) OR P(x) .

13. SCOPE RULES

        A name designates an object by two mappings: one from the name to a type and the other from the name to a "binding" (in the sense described in Section 4).

        The basic rule is that a name cannot be used in an expression if the value of either of the two mappings is undefined.

        The dual possibility of associating a name with a type through a declaration has been described at length in Section 4 and is not repeated here.

13.1. Establishing the Binding

The binding of an object is established by declaring the name one wishes to associate with the object in a predetermined place in the text, which depends on the category of the object itself (by "declaring", we mean that the name can appear in a declaration, in a header, or in the place of a declaration in the case of deferred binding).

Here is a table that indicates the place where a binding is established.

Object	Binding
Global definition	Definition in the DEFINITIONS paragraph
Local definition	Definition in the DEFINITIONS section of a function
Formal argument	When appearing in a function or macro header
Result argument	"
Quantified variable	When appearing after FORALL and EXISTS
Locally bound variable	When appearing between "(" and "!", or after FOR, LET or SOME

13.2. Scope of a Binding

We define the scope of a name as that part of a module specification where the name may be used in an expression, independently of the constraints imposed by type compatibility.

Generally, a binding is valid from the place where it was established up to some precise place, given below (although in some cases we give the scope itself rather than the place where the binding is destroyed).

Object	Binding
Global definitions	The whole module
Formal and result arguments	Valid only in the specification of the corresponding function or in the expression defining the macro
Locally bound variable	The expression(s) following the "!", INSET or "!" after FORALL, EXISTS, LET, SOME, and in set and vector constructors.

An important additional comment is that, although it is permitted to alter a valid binding temporarily (e.g., by using the name of a formal argument as a locally bound variable), this will mask the original binding for the scope of the new one. It seems that this practice should be avoided, inasmuch as it can bring only confusion in the specification.

                          14. COERCION RULES

As has been said in Section 5, a united type is very close to being a type by itself, and normally an expression of a united type should not match an expression of one of the components of the united type. However, such compatibility is permitted in some cases. The determination of these cases is based on what is known as the "coercion rules".

The first case of coercion is the TYPECASE expression, which should be the normal (and only) way to coerce "downwards", i.e., from a united type to a component type. Upward coercion (i.e., when an expression of a simple type is implicitly converted to a united type containing the original type as one of its components) may take place in the following cases:

    * When a formal argument to a function is of a united type, the corresponding actual argument may be of a component type.

    * In an expression of the form a = b, where a is a quoted V-function reference, the result argument of the V-function being of a united type, and b is an expression of a component type.

The actual rule is the same as above for TYPECASE expressions and actual arguments to functions. It is more general in the other cases, where an attempt to match a united type against one of its components is tolerated, albeit with a warning message which will hopefully remind the user that he/she is walking on dangerous ground. A warning message will also be issued when, in the constructs IF, SET, and VECTOR, the types of the constituent expressions do not match. However, this will not be the case for the binary operators on sets, UNION, INTER, DIFF, INSET, and SUBSET.

15. COMMENTS

        Although it has been barely mentioned so far, the language
has a comment feature: A comment consists of the sign "$" followed
by a sequence of characters without any space, parentheses, or square
bracket; or by a string of characters enclosed within two double-
quote signs (") (the string itself containing no double-quote); or by
any sequence of characters enclosed within two matching parentheses
or square brackets (in the case of parentheses, the sequence must not
contain any right square bracket that is not preceded in the sequence
by a left one).   More briefly, a comment can be described as a "$"
followed by any arbitrary LISP S-expression--see (Tei 75).

        A comment may appear at any place where a space is legal
(i.e., anywhere except in the middle of a syntactic unit).

16. MAPPING FUNCTION EXPRESSIONS

        The specifications for mapping function expressions follow a
slightly different syntax, although the "expression" part of the
language is exactly the same.

16.1. Module_Names

        A list of mapping functions specifications should begin with

        MAP module_1 TO module_2,..., module_k;

where module_1 is the module containing the functions and parameters
to be expressed as functions of elements of module_2,...,module_k;
module_1 is referred to as the "target" module.

16.2. TYPES

        The TYPES paragraph is similar to the one described for
module specifications, and it abides by the same rules.

16.3. DECLARATIONS

        The same conventions for deferred binding can optionally be
applied and the DECLARATIONS paragraph provides the same facility
towards this end.

16.4. DEFINITIONS

The same macro capabilities are provided in the DEFINITIONS
paragraph.

16.5. EXTERNALREFS

An EXTERNALREFS paragraph similar to the one optionally used
in a module specification is mandatory for mapping functions; it must
contain declarations for all the primitive objects (i.e., designator
and scalar types, parameters, and V-functions that are not derived)
appearing in the mapping function.

16.6. MAPPINGS

The MAPPINGS paragraph begins with MAPPINGS. It contains a
list of pairs of the form

        <object> : <expression>;
        or
        <symbol> : <type specification>;

where <expression> is any expression satisfying the rules described
earlier, and <object> is one of the following:

    * The name of a parameter of the target module

    * The name of a scalar type, in which case <expression> must be a
      set expression consisting of a list of as many expressions as
      there are constants in the scalar type definition;

    * A construct of the form

        <symbol> (<argument list>)

where <symbol> is the name of a visible V-function or a parameter
(with arguments) of the target module, and <argument list> is a list
of formal arguments in the usual sense.

The same scope rules apply, except that there is no result
argument.

The type of each expression, derived from the types of its
various components declared either in the declarations or in the
source modules, should be the same as that of the associated
parameter or V-function in the target module, or a set expression in
the case of a scalar type name.

In the second form, the symbol should be the name of a
designator type of the target module, and the type specification
should be legal in at least one of the lower modules.

17. THE TENEX-INTERLISP IMPLEMENTATION

The properties of specifications can be checked automatically by a "specification handler". Such a program has been written to run under the TENEX operating system on a PDP-10 machine; some of the conventions used (e.g., for strings) are a consequence of the conventions used in the implementation language (namely INTERLISP).

17.1. Strings

A string is the equivalent of an INTERLISP string, i.e., an arbitrary sequence of printable ASCII characters enclosed within two " (double-quote), where the characters " and % have to be represented as %" and %%.

17.2. Identifiers

An identifier (generally represented as <symbol> in this manual) is any sequence of up to 126 printable ASCII characters which is not a number, which does not contain any of the characters (,), [,], {, }, |, ,, ;, :, =, ~, -, +, <, >, *, /, ', ~, ?, $, space; and which does not start with either " or #. Note that 1%&a! is a perfectly legal identifier.

17.3. File Inclusion

If the character # appears after any of the characters listed in the previous paragraph, the next expression (in the INTERLISP sense) will be interpreted as a file name, and the program will take its input from that file until an end of file is reached, at which point it will come back to the original file. This may be repeated, i.e., the included file may itself include a third one, etc., although a file may not include itself, directly or indirectly.

18. CONCLUDING REMARKS

The reader may have noticed (by the very absence of such expressions) that nowhere have we spoken of "the value of a variable" or "the contents of a variable". Such phrases have been (carefully) avoided to stress one of the particularities of any specification language, i.e. the property of being nonprocedural; a name refers to a mathematical object, and never to an address or any other component of a computer. Indeed the language does not provide the

concept of a pointer, and this could be introduced only as a designator.

SPECIAL is often modified to deal with previously unsuspected problems. Part of the work to be done in order to design a good specification language is to understand fully the concepts involved and the specification methodology on which the language is based. A very desirable goal would also be the complete axiomatization of the language constructs, similar to the work done on Pascal by Hoare and Wirth (Hoa 73). We hope to come up with such a formalization in the (more or less) near future.

APPENDIX A : GRAMMAR

Legend: The grammar for the specification language is given in the so-called extended BNF, where <...> means that the enclosed symbol is a nonterminal of the grammar; [...] means that the enclosed construct is optional; {...}* means that the enclosed construct can occur 0 or more times; {...}+ means 1 or more times, and {... ! ... ! ...} means an alternation, i.e., any of the constructs listed can be used.

For convenience, all the nonalphabetic terminals have been enclosed within simple quotes (').

<symbol> stands for any identifier, <number> for any integer or real number.

```
ROOT                      ::= MODULE <symbol> [<types>] [<declarations>]
                                  [<parameters>] [<definitions>]
                                  [<externalrefs>] [<functions>]
                                  END_MODULE
                          ::= MAP <symbol> TO <symbol> { ',' <symbol> }* ';'

Appendix C*

COMMENTS ON "SECURITY KERNEL SPECIFICATION FOR

SECURE COMMUNICATIONS PROCESSOR"

(CDRL A018)

Contract F19628-74-C-0193,
Documents Review 1 February 1977
Department of the Air Force
Headquarters Electronics Systems Division (AFSC)
Hanscom Air Force Base, Massachusetts 01731

*Appendix C contains only those Air Force comments which remain
 pertinent. Many comments have been addressed in the current
 specification.

The top level specification shows significant progress on the part of Honeywell. In general, the functions provided in specification appear adequate. However, there are several potential difficulties with the current specification. These difficulties relate to the specification detail and style and the specific design decisions.

The specifications in their current state are more detailed than necessary for a top level specification. The top level specification need specify only what the kernel does. The current specification indicates how the kernel is implemented. Specifying too much detail has the drawback of complicating the proof of correspondence between the kernel and model elements. The extra detail makes the specifications longer which, in turn, make the proofs longer and more complicated. Also more detailed design decisions are more subject to change. Changes to the kernel design after the proofs could be costly because significant effort may be required to reprove the specification.

The detail of the current specification is not consistent. The report provides great detail about some aspects of the kernel but lacks detail regarding other aspects for no apparent reason. For example, the report details the effect of encountering a missing page (in spite of the claim that paging is invisible) but leaves out other details.

The memory manager interface does not appear adequate to permit implementation of typical memory management policies. The information available to the memory manager may not be sufficient to implement page management strategies such as least recently used or first-in, first-out. There may be additional data which would be helpful and not affect security. The current scheme appears to restrict the memory manager to random replacement policy.* Since the memory manager is a system high process, it seems that the memory manager could have access to any data maintained by the kernel. However, the memory manager's ability to modify kernel maintained data has to be controlled. Typical page replacement strategies employ sophisticated data bases (e.g. lists, queues, circular lists, etc.) and must monitor information from one invocation to another (e.g. pointers to where the search for candidates for removal ended on the last invocation, are often maintained, and used bits are turned off so that page use between successive invocations of the page replacement activity can be considered). The memory manager cannot reasonably obtain such information with the current interface. In fact, a memory manager interface that is both general and efficient many not be implementable.

---

*Since the kernel resets the page used indicators at each invocation of get_memory_data, the memory manager may select pages not used since previous invocation for swapping (see Section 4.6 for details).

The report claims that the memory manager is outside the kernel and can be implemented as an untrusted process. This claim is not readily apparent since the report does not provide a proof that the security provided by the kernel is independent of the memory manager and because the correct behavior of the kernel (the kernel's ability to fulfill its specification) depends on the memory manager. The kernel function get_memory_data provides the memory manager with system high information (the security level of the used and modified bits is the level of the process that caused the bits to be set). The add_pages_to_free_list is an interpretive write of kernel data. The level of the data provided to the kernel is system high. It must be shown that the data provided to the kernel is not visible to a lower level process. Because the correct operation of the kernel depends on the memory manager, the memory manager perhaps requires different treatment than other untrusted processes for policy reasons. Programs outside the kernel (not including programs upon which the kernel depends) should not be able to affect the operation of the memory manager. (For example, the memory manager could operate in a more privileged ring than that of the operating system, and the "core" security kernel could protect software in this ring just as it protects the software of its own ring.)

The previous paragraphs appear to conclude that the approach taken for the memory manager does not remove the memory manager from the kernel. Instead, the approach may simplify verification of the kernel (assuming the task of demonstrating that information returned to the kernel by the memory manager cannot be passed downward is simpler than proving correctness of the memory manager).

The rationale for not allowing process creation by untrusted processes is not apparent. The kernel must provide a capability to create and delete processes. The additional effort to permit untrusted processes to use these functions appears minimal and may result in other simplifications of the kernel such as the answering service.

There is a requirement that the top level specification for the SFEP provide multilevel network support. Functions in support of a multilevel network can be written in a general manner without a specific network in mind.

More specific comments are as follows:

Get_memory_data, add_pages_to_free_list - These functions provide for memory management. However, the exception should include a check for the caller being at system high.

Get_device_data - Since devices are not shared or pooled in the SFEP as are memory pages, there may be no use for this function or the device manager.

Async_device_read and async_device_write - Since these are hardware
functions, their specification must accurately reflect the hardware.
Are the first two exceptions that the device must be active and that
the segment number hasn't changed, actually checked by the SPM?*
Because these functions are performed asynchronously, the exceptions
may have to be considered different from those of other functions.

Device_wake-up - The effects of this function are very much like the
effects that may occur in async_device_read and async_device_write when
asynchronous exception conditions exist.

Send_message, receive_message - Cannot the message itself be an argument
to the function? That would eliminate most of the exceptions and some
of the effects. True, the message data will probably not move from its
original location in the user's segment, but most of the exceptions
listed are those performed by argument validation anyway, the details
of which are never specified.

The host-SFEP communication scheme lacks a method for communication
between system processes that may not have a device as a link. Can one
at this time rule out the need for a more general process-to-process
communication link? The MITRE specification employs a process-to-process
communication, with more generality and greater specification simplicity.
When one considers the possibility of an untrusted single level network
process in the SFEP that may have to communicate with more than one
Multics process, the generality may be necessary.

---

* The exceptions shown are checked by the SPM hardware.
